# Returns to Inventors\*

## Abstract

The return that inventors appropriate from their inventions forms a key incentive and remuneration mechanism for innovation. We utilize data on U.S. patents and their inventors linked to Finnish employer-employee data to estimate the effect of patenting on earnings. Inventors get a temporary 3% wage increase in the year of the patent grant. In addition, there is a 4-5% increase in earnings four years after the patent grant, which remains there for at least the following two years. The returns to inventors depend on the quality of the patent, as measured through the number of forward citations. Returns accrue through earnings, not capital income. Job changes do not affect returns. Initially owning the patent first yields negative returns but increases significantly the later returns, with the increases in years 5-6 after the patent grant being of the order of 15-30% instead of 4-5%.

\* We would like to thank Ari Hyytinen, Bill Kerr, Suzanne Scotchmer, Kathryn Shaw and Manuel Trajtenberg for discussions, and seminar participants at the XXX Annual Meeting of the Finnish Society for Economic Research, HECER, EARIE 2008, EEA-ESEM 2008, 3<sup>rd</sup> ZEW Conference on the Economics of Innovation and Patenting, and EALE 2008 for comments. Satu Nurmi and Margit Lahtinen at Statistics Finland were extremely helpful in matching the data. We would like to thank the Yrjö Jahansson Foundation for financial support. Väänänen also thanks the FDPE for financial support. The usual caveat applies.

# 1 Introduction

The extent of the literature on innovation and invention reflects the established fact that technological progress is a key determinant of economic growth. This literature emphasizes that innovations are essentially a product of human activity, made possible by the skill and effort of individuals. In view of this, it is surprising that very little is known of how individual inventors are rewarded. This paper takes a step towards filling this gap by empirically examining the financial returns to patent inventors and the sources of those returns. To this end, we construct a dataset where U.S. (USPTO) patents and their inventors from the NBER patents and citations data file (Hall, Jaffe Trajtenberg, 2001) are linked to Finnish employee-employer data containing detailed information on personal characteristics and earnings as well as information on the employers from 1988 to 1999. Studying Finnish inventors of U.S. patents has more than curiosity value: e.g. Trajtenberg (2001) singles Finland out as the only non-Asian country that matches Israel in growth in USPTO patents in the 1990s.<sup>1</sup> Understanding the role of monetary incentives of Finnish inventors may thus offer lessons of general applicability.

Inventors today mostly invent as a part of their job, as inventive activity is to a large extent organized in R&D laboratories in firms and other R&D performing organizations. Thus it is no surprise that the focus of existing research has been on innovation at the level of the innovating organization. However, a key to promoting innovation are not only the incentives that firms face, but also the incentives that individuals are provided with. These may take several forms: Rossman (1931) reports the

---

<sup>1</sup> See e.g. Figure 5 in Trajtenberg (2001).

survey responses of a group of over seven hundred inventors, including the most prominent inventors of the time, who were asked for their motives and incentives to invent. The most commonly cited reason was “love of inventing”, followed by “the desire to improve existing devices”. “Financial gain”, although clearly important, was only the third most frequently mentioned motive. There is clearly an element of current satisfaction (“on-the-job-consumption”) that research activity provides in addition to any financial rewards, as also noted by Levin and Stephan (1991), and emphasized in biographies of past inventors (Rossman 1931). Similar evidence is provided by Stern (2004), who finds that scientists employed by firms in fact “pay to be scientists”, i.e., accept lower earnings in return for being able to pursue individual research agendas and publish in scientific journals.

The importance of non-pecuniary incentives notwithstanding, economists have studied the role of monetary incentives in the innovative process. Aghion and Tirole’s (1994) incomplete contracts - analysis, for example, normalizes the non-monetary incentives to a constant, and studies the effects of monetary incentives. The standard theoretical foundation for providing employees with (monetary) incentives comes from principal-agent models. These models suggest that compensation should be tied to an informative signal of the level of effort (Holmström, 1979). While incentive schemes have been subject to empirical research (e.g. Bandiera, Rasul and Barankay 2005, and Lazear 2000), they have been less studied in the context of innovation. One exception is Lerner and Wulf (2007), who analyze how corporate R&D managers’ compensation affects innovation in firms. Their key finding is that when the corporate R&D head has substantial firm-wide authority over R&D decisions, long-term incentives such as stock

options are associated with a higher level of innovation (more heavily cited patents, patents of greater generality and more frequent awards).

The provision of incentives is not the only reason why the labor market would reward inventors. For example, being a patent inventor may work as a signal of the individual's ability and productivity and so result in a wage premium. Furthermore, such signaling can lead to improved firm-worker matches, thus raising earnings. Additionally, an invention represents knowledge, some of which is tacit and embedded in the individual, and this knowledge should earn a return in the labor market. A related point concerns knowledge spillovers: if firms want to prevent such spillovers, they may have to pay a wage premium to inventors in order to retain them. Evidence for this is provided by Møen (2005), who finds that while the technical staff in R&D-intensive firms first pays for the knowledge they accumulate on the job through lower earnings in the beginning of their career, they later earn a return on these implicit investments through higher earnings. Support for this view is also provided by Andersson et al. (2006), who find that firms with high potential payoffs from innovation pay more in starting salaries than other firms in order to attract star workers (workers with a history of higher earnings and wage growth), and furthermore, that such firms also reward these workers for loyalty. Van Reenen (1996) finds that technological innovation leads to higher average earnings in innovating firms, and interprets the result in accordance with theories of rent-sharing.

Finally, as in many other countries, there is a legal framework that provides a basis to expect inventors to earn a return on the inventions they produce while employed (the law on employee inventions in Finland, 29.12.1967/656). While giving the right to

the invention to the employer (in most cases)<sup>2</sup>, the law also rules that the employee has the right to reasonable compensation from the employer for the invention, taking into account the value of the invention. Similar legal provisions exist e.g. in Germany, and have been studied recently by Harhoff and Hoisl (2007). They address a question that is closely related to ours: Using survey data on German inventors of European patents, they study how the characteristics of the surveyed patent affect the share of the inventor's salary received as compensation for that patent.<sup>3</sup> The survey responses from the inventors indicate that the average compensation for one patent is 1.8 percent of annual gross income, and for all patents an average of 8.3%.

Monetary rewards to individuals' innovations may take various forms, including one-time bonuses, value-contingent payments, stock options, as well as wage raises. In any case, the returns ultimately show up in their earnings or possibly in terms of capital income. Thus the appropriate empirical approach to studying the individuals' returns to innovation follows the standard framework applied to study the e.g. returns to schooling, i.e. specifications similar to Mincer wage equations, where we use measures of invention generated from patent data. Patents offer a convenient, if not trouble-free, window on individual inventiveness and have been exploited in economic research at least since the 1950s (Schmookler 1957, Griliches 1992).

---

<sup>2</sup> Finnish law divides inventions into four groups in this respect: inventions in group A either came about as through a close relation with the job of the inventor, and utilization of the invention fits into the activities of the employer or came about as part of the job of the inventor (no matter whether the utilization fits into the activities of the employer or not). In this case, the employer owns the invention if it so chooses. Inventions in group B came about in a different relation to the job as those in group A, but fit into the activities of the employer. For these inventions, the employer has user rights, but must negotiate over any larger rights. Inventions in group C came about without a connection to the job of the inventor, but the utilization falls into the activities of the employer. The employer has then the right to negotiate over use rights first. Inventions in group D came about without a connection to the job of the inventor and the utilization does not fall into the activities of the employer. The employer has no rights in this case (Mansala 2008).

<sup>3</sup> Their survey contains a question about this share, but apparently no questions on levels of monetary compensation. Harhoff and Hoisl also offer a very nice discussion of legal compensation schemes for inventors in various countries.

We estimate the effect of granted patents on earnings over time, and investigate its dependence on the value of the innovation, proxied by a quality measure based on the citations received by the patent (following Trajtenberg 1990, and several later papers). In addition, we also explore some possible sources of these returns. We analyze the dependence of the returns on the ownership of the intellectual property by comparing the returns to inventors who initially own the patent to the returns when the patent is assigned to an organization. We also examine whether employer changes after the patent grant affect the returns. Having access to panel data at the individual level, together with the variation over time in our variable of interest, enables us to control for unobserved individual heterogeneity, which is often a problem in exercises of similar nature, such as in estimating the returns to schooling (see e.g. Card 2001). Furthermore, the lag between the time of an invention and the patent grant enables us to treat granted patents as predetermined variables.

We find that inventors get a temporary increase in their earnings close to 3% in the year of the patent grant, presumably corresponding to a one-time bonus for being awarded a patent. In addition, there is a 4-5% increase in earnings four years after the patent grant, which remains there for at least the following two years, possibly representing a permanent wage increase. We also find that the returns to being a (patent) inventor depend on the quality or value of the patent, and these quality-dependent returns are first realized three years after the granting of the patent, coinciding with the time it typically takes to learn the value of a patent (Pakes 1986, Lanjouw 1998). Similar to the value of patents to firms, and in line with the findings of Harhoff and Hoisl (2007), the returns to inventors thus seem heavily skewed, and linked to citations (Trajtenberg,

1990). It seems natural to think of rewards to patenting as part of “pay for performance”, the increase in which has recently been shown to explain a large part of growth in male wage inequality in the U.S. from the 1970s to the 1990s (Lemieux, MacLeod, Parent 2008).

Examining more closely the reward structure reveals that job changes (at least after the patent grant) do not affect the returns to inventors. Inventors are also not rewarded through changes in capital income. When separating the returns by the ownership of the patent (at the time of the patent grant) we find that those inventors who initially own their patents eventually earn substantially higher rewards than those inventors who do not have the intellectual property rights over their invention: The returns to inventors who initially own their patents is of the order of 15-30% in the 5<sup>th</sup> to 6<sup>th</sup> year after patent grant. This difference is not explained by higher quality of inventor owned patents: the number of citations to inventor-owned patents is lower than to company-owned patents. This finding suggests that conditional on the quality of the patent, owning the intellectual property significantly increases the returns to inventors.

A number of other findings are also of potential interest. We find that conditional on being an inventor, there is a male-female wage gap of 20%. The returns to age (experience) are high, of the order of 10-12%, possibly mirroring the results of Møen (2005) discussed above, but the returns to tenure are low (less than 1%).

The rest of the paper proceeds as follows. Section 2 describes the data. Section 3 presents the empirical framework. Section 4 presents the results and Section 5 concludes.

## 2 Data

### ***2.1 Matching USPTO and FLEED data***

Our source of information on inventions and inventors is the NBER patents and citations data file (Hall, Jaffe Trajtenberg, 2001) on U.S. Patent Office (USPTO) patents. In the past few years, there have been some research projects making use of large scale inventors' data. Most notably, Trajtenberg et al. (2006) have developed a computerized matching procedure to identify inventors in the NBER patent data. Some studies have used smaller scale data: Kim, Lee and Marschke (2004) use matched firm-inventor data from the pharmaceutical and semiconductor industries to study the relationship between firm size and inventor productivity. We go a step further than the previous studies and match inventor data to the employee records in a longitudinal employer-employee dataset of the Finnish working-aged population (FLEED) that resides at Statistics Finland. The FLEED is a register-based dataset that contains detailed information on individuals and their characteristics, in particular their annual earnings, as well as firm-level information on their employers.

The NBER patent data contains the names of all inventors of a given patent, and information on their address (at a minimum, the municipality of residence). In Finland, each resident is given a unique identifier (the personal identity code), which is contained in the Finnish Population Information System (FPIS) together with basic personal information, including the address and municipality of residence. With the aid of the Population Information System, inventor information from the NBER patent data can be linked to their personal identity codes. These personal identity codes are also contained in

the FLEED (in encrypted form), enabling the linking of inventor information with it.<sup>4</sup> Those Finnish patents from the NBER data that are assigned to Finnish companies have also been linked to their assignee firms in the FLEED. This provides us with an additional link we can use to help us identify the inventors. In cases where the name and residence information in the inventor data matches more than one personal identity code from the FPIS, we also utilize this link between the patent inventor and the patent assignee, allowing us to search for the correct personal identity code from among the employees of the assignee firm. Altogether, this information helps us in solving a key issue that has hampered progress in studying inventors: the matching of inventors from patent documents to other data.

We use USPTO patents rather than Finnish patents, because they should be more valuable. Grönqvist (2007) has estimated that the average value of a Finnish patent is of the order of only 5000€ reflecting the small size of the Finnish market. Using USPTO data will also make our results comparable to other studies using the same data.

The data construction proceeded as follows. Using the full name and the municipality of residence on the inventor record (as well as the full address where available), together with the patent application year, the FPIS was searched for matching records and all matching personal identity numbers were linked to the inventor record. For some, this resulted in a unique match, while for others a number of potential identity numbers matched the inventor information. In order to determine the right identity for the inventor, we utilized the link between the patent inventor and the assignee firm to search

---

<sup>4</sup> The process of linking the inventor records to personal identification codes was done at the Statistics Finland by their own personnel under strict confidentiality, and we never had access to any information that would have enabled the identification of individual people from the data.

the personal identity codes of all the employees in the assignee for matches with those linked to the inventor record.

For those individuals for whom more than one personal identity number was found from the population register, the identification of the correct individual was based on the assumption that they are employees of the patent assignee firm. While we expect this to hold true for the majority, in some cases this may lead to misidentification of the inventor. Thus we may have assigned a patent to some non-inventors, and at the same time failed to assign the patent to its proper inventor. If this is the case, it introduces some measurement error into our patent variable and biases our estimates downward.

Unfortunately, though not surprisingly, we were unable to identify and link all the patent-inventor records to the employee records, for two reasons. First, for some inventor records, the search from the population register produced no match. This could be due to misspellings in the names or incorrect information for some other reason. Second, for some of those inventor records for which several matching identity numbers were obtained from the population register, more than one of these identity numbers were also found among the employees of the patent assignee firm. Without a unique match, we failed to identify and link the patent to any individual, so that these inventors are not included in our sample.

Taking from the NBER patents data all the patents whose country code is FI, and which were applied for between 1988 and 1999, and linking these patents to their inventors, whose country code is FI, we end up with 8065 inventor-patent records. From these, we manage to identify and link 5905 records to the FLEED, consisting of 3253 individuals. For our empirical analysis, we limit the sample to observations from the year

1991 onwards, because the linking of inventors and patents to the FLEED is based on the application year of the patent, but our analysis uses the grant year of the patent. The typical lag from the patent application to the grant is between one and three years, so for most of the cases, we are able to match a patent inventor to a granted patent from 1991 onwards. The resulting sample is an unbalanced panel, with 91% of the individuals appearing in the data for all the nine years, resulting in a total of 28212 observations.

## ***2.2 Samples and descriptive statistics***

The process described above generates our data on inventors, i.e., individuals that have at least one USPTO patent during our observation period. We limit our estimation sample to individuals who are full-time employees at the end of the years in which we measure their earnings (i.e. remove those classified as entrepreneurs, unemployed, students, retired, in military service or otherwise out of the labor market). Removing from the sample observations for which there are missing values in any of the variables we need, we are left with a sample of 15996 observations on 2156 individuals. For our full specification, which includes six lags of the patent variable, the sample consists of about 4938 observations on 1789 individuals.

Table 1a presents some descriptive statistics for this sample for the years 1991, and 1995-1999. We see that the individuals in this sample are predominantly male (92%), on average 39 years old in 1991 (45 years old in 1999), and employed by their current employer (tenure) for 8 years on average in 1991. The mean annual earnings in the sample is about 37 000 Euros in 1991 and they increase throughout the time period, reaching over 50 000 Euros in 1998 (all converted to 1999 money). The mean earnings in 1999 are at 80 000 Euros with a very high variance. Table 1b presents the descriptive

statistics conditional on having been granted a patent that year: the number of individual inventors has almost tripled over the period of the 1990's from 196 to 560; the mean number of patents per inventor ranges from 1.2 to 1.4. The patent quality, i.e. the mean number of expected lifetime citations received per patent, varies around 13 and shows no particular trend. Table 1c presents the levels and fields of education for the sample. The inventors are fairly highly educated, with more than half of the inventors having a masters degree or a doctorate. Most of the inventors have an engineering degree (78%). Table 1d shows the number of observations in the main industry sectors represented in the sample, with 70% of the individuals working in the following 5 sectors: manufacturing of chemicals and chemical products; machinery and equipment; radio, tv and communication; medical, precision, and optical instruments; and provision of business services.

The number of firms represented in the data is 224 in 1991 and 528 in 1999, with a total of 936 different firms over the whole time period. The distribution of the number of individuals per firm is skewed, with (in 1999) over 350 firms employing just one inventor, 60 firms employing two inventors, 30 firms with 3 inventors, and only three firms with more than 100 inventors.

[Tables 1a, 1b, 1c and 1d here]

In Figure 1 we present the histogram of the number of patents per inventor over our sample period. The great majority of them (60%) have just one patent over the whole time period, while about 20% have two patents and the most inventive of them as many as 23 patents. To gain further insight into this, Figure 2 presents a histogram displaying the frequency of observations with  $n$  patents. This distribution is also heavily skewed

with a mass at zero patents: almost 12993 observations with zero patents in a given year (not shown in the figure), 2422 observations with one patent, and 409 with two patents. Figure 3 shows the distribution of citations for observations with at least one patent. This distribution is also heavily skewed to the left with a long right tail.

[Figures 1 - 3 here]

We have 127 inventor-patent grant observations where the patent is owned by the inventor(s) at the time of granting the patent, while the rest are observations where the patent is assigned to an organization (mostly companies, so we refer to these as corporate-owned patents). Comparing the number of citations by ownership we find that inventor-owned patents receive fewer citations than those owned by organizations: the mean number of citations for inventor-owned patents is 7.32 and that for corporate-owned patents 10.27.

### 3 The empirical framework

We estimate equations of the following form:

$$\ln(w_{it}) = X_{it}\beta + \sum_{j=0}^{\tau} \gamma_{j+1} patent_{i(t-j)} + \alpha_i + \mu_t + \varepsilon_{it}, \quad (1)$$

where  $\ln(w_{it})$  refers to the log of annual wage income,  $X_{it}$  is a vector of person- and firm-level characteristics,  $\alpha_i$  is an individual-specific unobservable fixed effect, possibly correlated with the variable patent,  $\mu_t$  is a year dummy, and  $\varepsilon_{it}$  is the error term. Personal characteristics include the person's age and its square, a vector of 42 dummy variables for the level and field of education, gender, tenure with the current employer, and the number of months employed during the year. Firm characteristics include the

sector of the firm, the number of employees in the firm, and its location regionally (NUTS2: 5 location dummies<sup>5</sup>).

The variable  $patent_{it}$  is a variable capturing the individual  $i$ 's inventions in period  $t$ . The simplest measure of invention we use is a patent count, i.e., the number of patents granted in a given year in which the individual is listed as an inventor. Because inventions can affect earnings in subsequent years, not just in the year of the patent grant, we include  $\tau$  lags of the patent variable in order to estimate any long-term wage effects of innovation. We experiment with as many lags as the data enables.

We also explore the implications of patent value or quality on the inventors' earnings by using forward citations to the patent. A number of studies have shown that there is substantial heterogeneity in the value of innovations, and that this distribution is highly skewed, e.g. by using patent counts and renewal decisions (Pakes 1986, Lanjouw 1998, Grönqvist 2007), survey questions on patent value (Harhoff, Narin, Scherer and Vopel, 1999), and from patent citations (Trajtenberg 1990, Hall, Jaffe and Trajtenberg 2005). Given that the returns to firms from patents are highly variable, one might expect that the rewards that employers pay to inventors are also based on the value of the innovation.

We use both the within and first-differencing transformation to identify the effect of patenting on an individual's wage. The key aspect is that any unobservable individual time invariant factors are removed by these transformations. Importantly, this relieves us of the ability bias typically encountered in the returns to schooling studies (see Card 2001 for a review of the schooling studies). Both the within and first-differenced estimators are

---

<sup>5</sup> The NUTS 2 is a five-level regional classification system of the European Union. In Finland the five major regions are: Southern Finland, Western Finland, Eastern Finland, Northern Finland, and Åland.

consistent under the assumption of strict exogeneity:  $E[\varepsilon_{it} | Z_{i1}, \dots, Z_{iT}, \alpha_i] = 0$ . We expect no contemporaneous correlation between the error term and the patenting variable, because a patent granted in year  $t$  has in effect been (pre)determined before year  $t$ . The lag between the years of patent application and granting of the patent is on average 2 years in our data. Therefore the effort into developing the innovation has been put in at least a couple, probably more, years before the granting of the patent. One possible worry about the strict exogeneity condition is that future wage shocks may be correlated with the current period value of the patent variable, for example through labor markets treating patenting as a signal of (permanent or at least long-lasting) productivity. However, this is part of the effect we estimate and is captured by the inclusion of the lagged values of the patent variable. If, on the other hand, the realization of patents in the future is correlated with the contemporaneous error term in the wage equation, the strict exogeneity condition would be violated. This could happen, for example, through changes in jobs either within or between firms, if a job change results in a better match between inventor and firm and also improves the patent productivity of the inventor. We apply a test of strict exogeneity and do not reject it.

## 4 Results

### 4.1 Base specification

In Table 2 we present the results from estimating our base specification with the variable patent being the number of patents granted to individual  $i$  in year  $t$ . While our preferred estimation methods are fixed effects and first-differencing, we also report the results from pooled OLS for comparison. The pooled OLS estimate of the returns to inventors is

0.035, the fixed effects estimate is 0.016, and the first-difference estimate is 0.013. The magnitude of the OLS estimate reflects the upward bias generated from unobserved individual heterogeneity, as expected. These results indicate that the average increase in earnings due to having an invention being granted a patent is around 1.5%.

[Table 2 here]

Some of the control variable coefficients are of interest: The age premium (the return to experience) is relatively high (coefficient on age circa 0.1 and that of squared age -0.001); the coefficient on tenure<sup>6</sup> (measured in years) is only 0.002 – 0.009, but that on the female dummy is -0.21 (OLS coefficient). Firm size has a positive effect on earnings (large firms pay higher earnings). Most of the year dummy-coefficients are significant, as are many of the education and sector indicators' coefficients.

In order to test whether inventors are rewarded already at the time of the patent application, we ran a specification where we also include the number of patent applications together with patent grants in year  $t$ .<sup>7</sup> We find no significant effect of patent applications on earnings; the coefficient on the patent grants remains the same.

## **4.2 Including lags**

We next investigate whether the effect of patenting on wage is a permanent increase in the wage level (e.g. a wage raise) or a temporary one (e.g. a bonus) by including lags of the patent variable. Including lags is also important because patent grants may be correlated over time and thus introduce an omitted variable bias when not included in the estimations (in other words, violation of the strict exogeneity).

---

<sup>6</sup> We also tried specifications including the square of tenure, which was mostly insignificant and did not affect our results.

<sup>7</sup> For these regressions, we are forced to exclude the most recent years of our data (1997-1999), because we do not observe the patent applications for patents granted after 1999.

We run a series of regressions where we include lagged values of the patent variable, experimenting with one to six lags. We also test the strict exogeneity assumption by including the lead of the patent variable in our fixed effect model, and by including the levels of the patent variables in our first-differenced model (see e.g. Wooldridge 2002, ch. 10.7.1). We cannot reject the null in either case. In Table 3 we present the results from the estimations with six lags. The coefficients of the control variables (age, tenure, gender) hardly change. In all the estimations, the coefficient of the current value of patent remains positive, and in fact goes up (0.050 in OLS, 0.022 in FE, and 0.028 in FD). This suggests that there indeed is an omitted variable bias in the base specification results.<sup>8</sup> In addition, the fourth, fifth and sixth lags get a positive significant coefficient in the fixed effects and first differenced regressions, ranging from 0.04-0.05. These results indicate that, first of all, there is a temporary wage increase in the year of being granted a patent in the order of just below 3%, and in addition to that, there appears to be a longer lasting, possibly permanent, effect increasing earnings from 4 to 5 percent four years after the invention is patented. The fact that this wage increase comes a few years after the patent grant may be related to the fact that it typically takes three to four years to learn the value of the patent (see Pakes 1986 and Lanjouw 1998 for German, UK and French patents and Grönqvist 2007 for Finnish patents). For example, Pakes (1986) finds that only 1.2 (0.5)% of French patent owners learn that their patent has no value in the 3<sup>rd</sup> (4<sup>th</sup>) year of patent life, and that the probability of learning a better use of the patent is only 0.1 (0.0)% in the 3<sup>rd</sup> (4<sup>th</sup>) year of patent life. His respective numbers for

---

<sup>8</sup> Intuitively, what happens in the base specification is that the (fourth – sixth) years after the patent grant are wrongly allocated into the control group of “no patent grant” – years, raising the average wage earned while in the control group, and thereby inducing a downward bias in the base specification patent coefficient.

German patents are even lower. We investigate next whether patent quality affects returns to inventors by using citations as a measure of the quality or value of the patent.

[Table 3 here]

### **4.3 Accounting for the quality of the patent**

The effect on earnings of having made a patented invention is likely to depend on the value of the patent. The number of citations received by a patent has been shown to be a fairly good proxy for the value of the patent, so we run the regressions including lags of the number of citations received by the inventor's patents together with the current period patent count. Using citations suffers from the problem of truncation, as citations to a patent arrive over long periods of time, but we only observe them until the last year of the available data.<sup>9</sup> We adjust these citation counts using the results in Hall, Jaffe, and Trajtenberg (2001) to remove the effects of truncation. These adjustments provide us with an estimate of the total number of citations a given patent will receive in its lifetime. We acknowledge that these estimates will be somewhat noisy, because for the patents in our data we only observe citations for the subsequent 3-15 years. Typically, the prime citation years for a patent are roughly 3-10 years after the grant (Hall, Jaffe, and Trajtenberg, 2005). The less citation years we observe for a patent, the noisier these estimates are.

The results of these estimations are presented in Table 4. We find that between three and six years after the patent grant (and possibly permanently), the number of citations received has a positive effect on the inventor's earnings, with every 10 citations

---

<sup>9</sup> Here we make use of the updates to the NBER patent data, available from Bronwyn H. Hall's website, allowing us to observe the number of citations received by the patents up until 2002.

received increasing the inventor's wage by around 3-5% (the estimates from the FD estimation are slightly lower than from the FE, and only weakly significant). These results lend support to the notion that the returns to inventors depend on the value of the patent, and are realized three years after the patent grant once the value of the invention is learned. The immediate effect of the patent grant remains. Similar to the value of patents to firms, and in line with the findings of Harhoff and Hoisl (2007), the returns to inventors thus seem heavily skewed. These findings lend further support for the claim, originating from Trajtenberg (1990), that citations are a measure of patent value.<sup>10</sup>

[Table 4 here]

#### **4.4 Reward mechanisms**

To extend our analysis from the level of returns to inventors to the sources of returns, we do three things: First, we study whether it is changes of employer that yield the estimated returns. As patents are public information, the granting of a patent may make the inventors "more visible" and/or more valuable to other employees and returns to inventors could then be realized through job changes. Second, patents are not just a measure of invention: they also dictate who has the intellectual property over a given invention at the time of the patent grant, and (not) owning the intellectual property may affect the return to inventors, keeping the value of the patent constant. These returns may be realized through a variety of mechanisms such as licensing fees or through the sale of the intellectual property rights, or simply by increasing the value of the individual in the job market. We therefore study the effect of (not) owning the intellectual property at the

---

<sup>10</sup> Trajtenberg (1990) found that citations reflect the social value of inventions. We find that they reflect the private (inventor) value of inventions.

time of the patent grant. Concentrating on ownership of intellectual property at the time of patent grant allows us to capture also the returns to inventors generated through subsequent sale of the intellectual property rights. Finally, we change our dependent variable to include capital income. As discussed in the introduction, if patents are valuable to the employer and producing patents requires effort (that is hard to monitor or measure), the employer may resort to providing incentives that generate capital income as well. It should be noted that since 1995 in Finland, stock options have been taxed as income and not as capital gains and thus are included in the dependent variable in our earlier regressions.

Turning first to the question of returns due to employer changes: The data shows that about 4% of the individuals change employers in a given year, and that over the time period of six years (from 1993-1999), 22% of the individuals have changed employers at least once. To study the possibility that the returns to inventors are generated through changes in jobs, we include a series of indicator variables and interactions between them and the patent variables to capture the effect of job changes between the year of the patent grant and the year when income is measured. To illustrate, consider an individual who obtained one patent three years ago, and changed her job last year. For her, the interaction between the job change indicator and the count of patents obtained three years ago would take the value one. This interaction allows us to separately identify the returns coming from patents obtained three years ago to those individuals who have subsequently changed jobs and to those who have not. Adding these variables into the specification containing lags of patent counts, we find that neither any of the new indicators, nor any of the interactions obtains a significant coefficient. Furthermore, our point estimates for the

patent count variables are virtually unchanged. While this result suggests that actual job changes do not generate any extra returns to inventors, it does not mean that the existence of the possibility of changing jobs would not be a causal factor behind the returns we estimate.

In contrast, we do find that the ownership of intellectual property rights is a significant mechanism through which the returns to inventors are generated. We separate the patents into two classes: those owned by a company (whether the employer of the inventor(s) or some other) at the time of the patent grant, and those owned by the inventor(s). We then re-estimate the model with lags of patent counts for both types of patents. The coefficients of the patent variables from both a fixed effects and a first-difference estimation of this specification are reported in Table 5. From that Table it is obvious that the reward structures are different when we condition for ownership: inventors who initially own the patent first forego some of their earnings (possibly due to efforts in developing and commercializing the invention), but later earn returns higher than those earned by inventors of patents owned by a firm. Patents initially owned by the inventor(s) yield negative returns in the year of the patent grant and the year after that (inventors forego 7 and 15% of their annual earnings in these years), but later yield returns of circa 15% in the 5<sup>th</sup> year after patent grant (the point estimate in the FE model is 20%, but insignificant), and returns of around 30% in the 6<sup>th</sup> year (the point estimates are similar from both FE and FD, but the first-difference estimator is insignificant). The coefficients for the patent count variables when the inventor is not the initial owner are very close to those we obtained earlier (see Table 3), with returns in years 4-6 after the patent grant between 3.5 (6<sup>th</sup> year in the fixed effects regression) and 5.1% (5<sup>th</sup> year in the

fixed effects regression). These differences in returns are not explained by the inventor-owned patents being of higher quality: as reported above, the number of citations is lower for (initially) inventor-owned patents than others.

A possible explanation for the initial negative returns to inventors who own their patents is that after obtaining a patent, they invest in increasing the value of the patent. Such investments could include development of the technology, spending time informing potential buyers about the technology and/or organizing the licensing or sale of the patent. Such activities could lead to a short-term decrease in earnings.

[ Table 5 here]

Finally, turning to the question of whether inventors are rewarded through capital income -generating mechanisms, we re-estimate our model by changing the dependent variable to be the logarithm of the sum of wage and capital income (instead of being the logarithm of the former only). Estimating the model with lagged patenting variables (and a fixed effects estimator) we find that the coefficients of the lags for 4<sup>th</sup> to 6<sup>th</sup> year are significant (4<sup>th</sup> year only at 7% level, others at 1% level) with point estimates of 0.038, 0.052 and 0.04. These are all slightly lower than those reported in Table 3. Converting these per cent returns to monetary rewards we find that the monetary rewards at the wage level are almost exactly the same as when including both wage and capital income: using the mean wage and capital income over the years 1997-1999 as our base, the estimated monetary returns at the wage level are 2550€ in the 4<sup>th</sup> year after the patent, 3260€ in the 5<sup>th</sup> and 2900€ in the 6<sup>th</sup>. These compare to monetary returns of 2560€, 3500€ and 2700€ when capital income is included in the dependent variable. It thus seems that the job market does not reward inventors through capital income. One reason why we find no

extra returns in capital income is probably that stock options are in fact taxed (and reported) as annual wage income.

## **5 Conclusions**

The engine of economic growth is technological progress; the engine of technological progress is human inventiveness. We address the question of the returns to individual inventors by estimating the effect of obtaining a U.S. patent on the earnings of Finnish inventors over subsequent years. Finland is one of the countries that has improved its rate of invention, measured by U.S. patents, the most over the last decades (Trajtenberg 2001). Understanding the role of monetary incentives in bringing this change about should offer lessons of more general applicability. Also, our results may contribute towards explaining wage inequality arising through performance pay.

Our results indicate that, first there is a close to 3% temporary increase in earnings in the year the patent is granted, probably representing a one-time bonus; second, there is a 4-5% increase in earnings four years after the patent grant, which remains there for at least the following two years, possibly representing a permanent wage increase; third, the returns to being a patent inventor depend on the quality or value of the patent as measured by the expected lifetime citations received by a patent. These quality-dependent returns are first realized three years after the granting of the patent, coinciding with the time it typically takes to learn the value of a patent.

We find that the rewards are no different for inventors who change jobs and those who stay with the same firm. The possibility of job changes may still be a reason behind

the estimated returns. Our results indicate that the rewards accrue as changes in earnings (incl. stock options) rather than as increases in capital income.

We find that the returns to inventors depend not only on the quality of the invention, but also on ownership of intellectual property: Having ownership of the intellectual property when the patent is granted first yields negative returns but later increases the estimated returns in years 5-6 after the patent grant 4-6 fold, from around 4% to between 15 and 30%. This result is not explained by quality differences between inventor-owned and other patents.

Robust standard errors below		
*** p<0.01, ** p<0.05, * p<0.1		

Notes: The dependent variable is log annual wage income. All regressions include dummies for the field and level of education, dummies for the sector of the firm, dummies for the firm's regional location, and year dummies. OLS are the results from pooled OLS estimations with clustered standard errors, FE are the results from using the within (fixed effects) estimator, and FD are the results from the first-differenced regressions.
